February 2026

Abstract

Land use change—particularly deforestation, agricultural expansion, and urban encroachment—is the primary driver of biodiversity loss, yet monitoring these changes at global scale with sufficient spatial and temporal resolution for conservation intervention remains a formidable challenge. We present ZooSat, a deep learning pipeline for continuous ecological monitoring from satellite imagery that detects land use changes at 10-meter spatial resolution with weekly temporal granularity. ZooSat introduces a *Temporal Siamese Network* (TSN) architecture that processes paired multi-spectral satellite image sequences to detect and classify ecological change events, achieving 94.2% change detection accuracy and 87.8% change type classification accuracy on a new benchmark dataset spanning 12 biomes. We develop a *Habitat Fragmentation Index* (HFI) computed from detected changes using landscape ecology metrics, providing a quantitative measure of habitat connectivity degradation that correlates strongly ($r = 0.87$) with field-measured biodiversity loss. A novel *Conservation Alert System* (CAS) processes change detections through a priority ranking model that accounts for ecological sensitivity, protected area status, species richness, and change magnitude to generate actionable alerts for conservation organizations. Over 18 months of operational deployment covering 2.4 million km² across 47 protected areas in 14 countries, ZooSat generated 12,847 conservation alerts, of which 89.3% were validated as genuine ecological threats. The system detected 234 deforestation events an average of 11.2 days earlier than existing global forest monitoring systems, enabling rapid response interventions that prevented an estimated 4,200 hectares of additional forest loss.

Keywords: remote sensing, change detection, deforestation, habitat fragmentation, deep learning, conservation monitoring

1 Introduction

The conversion of natural habitats to human-dominated land uses is the single largest driver of biodiversity decline, responsible for more species extinctions than climate change, pollution, and overexploitation combined [Maxwell et al., 2016]. Tropical deforestation alone eliminates an estimated 10 million hectares of forest annually [FAO, 2020], while less conspicuous forms of habitat degradation—selective logging, agricultural intensification, infrastructure development—erode ecosystem integrity across all biomes [Watson et al., 2018].

Satellite remote sensing provides the only feasible means of monitoring land use change at scales relevant to global biodiversity conservation. The Landsat archive offers 50 years of

multispectral imagery at 30-meter resolution [Wulder et al., 2019]. The Sentinel-2 constellation provides 10-meter resolution with 5-day revisit frequency [Drusch et al., 2012]. Commercial constellations (Planet, Maxar) achieve sub-meter resolution with daily coverage.

Despite abundant data, three challenges limit the effectiveness of satellite-based ecological monitoring.

First, *change detection accuracy*. Traditional approaches based on vegetation indices (NDVI differencing) or pixel-level classification comparison produce high false-positive rates due to phenological variation, atmospheric artifacts, and cloud contamination [Zhu, 2017]. Deep learning methods have improved accuracy but require extensive labeled training data that is expensive to produce for diverse global ecosystems [Yuan et al., 2021].

Second, *ecological interpretation*. Raw change detection identifies where land cover has changed but not what the change means for biodiversity. A detected change could represent catastrophic deforestation, natural seasonal variation, prescribed burning, or sustainable agriculture—outcomes with vastly different conservation implications [Redford, 2003]. Translating remote sensing signals into ecologically meaningful assessments requires integration with landscape ecology principles.

Third, *actionable timeliness*. Global forest monitoring systems such as Global Forest Watch [Hansen et al., 2013] provide monthly to annual updates. For conservation enforcement, this latency is often too slow: illegal deforestation operations can clear hundreds of hectares within days, and by the time satellite-based alerts arrive, irreversible damage has occurred [Finer et al., 2018].

We present ZooSat, a deep learning pipeline for continuous ecological monitoring that addresses all three challenges. Our contributions are:

1. **Temporal Siamese Network (TSN)**: A deep architecture that processes paired sequences of multi-spectral satellite images to detect and classify ecological change events with 94.2% accuracy, handling cloud contamination and phenological variation through temporal attention mechanisms (Section 3).
2. **Habitat Fragmentation Index (HFI)**: A landscape-scale metric computed from detected changes that quantifies habitat connectivity degradation in real-time, providing a leading indicator of biodiversity decline (Section 4).
3. **Conservation Alert System (CAS)**: A priority-ranked alert pipeline that translates change detections into actionable conservation intelligence, delivering alerts an average of 11.2 days faster than existing systems (Section 5).

2 Related Work

2.1 Satellite-Based Change Detection

Change detection from satellite imagery has evolved through three generations. First-generation methods used algebraic operations on spectral bands: image differencing, image ratioing, and change vector analysis [Singh, 1989]. Second-generation methods employed machine learning classifiers (random forests, SVMs) on hand-engineered features [Zhu, 2017]. Third-generation methods use deep learning for end-to-end change detection.

Among deep learning approaches, Daudt et al. [2018] introduced fully convolutional Siamese networks for change detection. Chen et al. [2020] proposed a spatial-temporal attention network for bi-temporal change detection. Zheng et al. [2021] demonstrated that transformer architectures achieve state-of-the-art change detection accuracy. However, most work focuses on urban change detection rather than ecological monitoring, and processes image pairs rather than temporal sequences.

2.2 Deforestation Monitoring

Global Forest Watch [Hansen et al., 2013] provides the most widely used deforestation monitoring, based on Landsat-derived tree cover change maps updated annually. GLAD alerts [Hansen et al., 2016] improved timeliness to monthly updates using Landsat-8 data. Planet-NICFI [Planet, 2020] provides high-resolution basemaps for tropical forest monitoring but relies on visual interpretation rather than automated detection.

Maretto et al. [2020] applied deep learning to Sentinel-2 for Amazon deforestation detection, achieving 88% accuracy. Ortega et al. [2021] developed near-real-time deforestation detection using Sentinel-1 SAR data, robust to cloud cover but at lower spatial resolution. None of these systems integrate change detection with ecological impact assessment or conservation-prioritized alerting.

2.3 Landscape Ecology Metrics

Landscape ecology quantifies habitat pattern through metrics such as patch area, edge density, connectivity indices, and fragmentation measures [McGarigal, 2012]. Haddad et al. [2015] demonstrated that habitat fragmentation reduces biodiversity by 20–75% depending on scale and ecosystem type. Fahrig [2017] analyzed the relative effects of habitat loss versus fragmentation per se, finding that loss is the dominant driver but fragmentation contributes additional negative effects through edge effects and isolation.

Remote sensing-based fragmentation assessment has been limited to static analyses [Vogt et al., 2007] rather than continuous monitoring. Our HFI provides the first real-time fragmentation metric derived from change detection.

2.4 Conservation Alert Systems

Early warning systems for conservation include the FIRMS fire detection system [Giglio et al., 2016], which detects active fires from MODIS and VIIRS data within 3 hours. Finer et al. [2018] developed the Real-Time Deforestation Alert System (RAISG) for the Amazon using Sentinel-1 radar data. Brancalion et al. [2020] proposed a prioritization framework for forest restoration but not for active threat response.

3 Temporal Siamese Network

3.1 Architecture Overview

The TSN processes a temporal sequence of multi-spectral satellite images to detect ecological changes. Unlike bi-temporal methods that compare only two images, TSN ingests a sequence of T images spanning the monitoring period, enabling robust change detection that distinguishes persistent land use change from transient events (cloud shadows, seasonal variation, short-term flooding).

The architecture consists of three components:

1. **Spatial Encoder:** A shared convolutional backbone that extracts spatial features from each image independently.
2. **Temporal Attention Module:** A transformer-based module that models temporal dependencies across the image sequence, identifying persistent changes while suppressing transient artifacts.
3. **Change Decoder:** A fully convolutional decoder that produces pixel-level change maps with class labels.

3.2 Spatial Encoder

The spatial encoder E_ψ processes each multi-spectral image $\mathbf{x}_t \in \mathbb{R}^{H \times W \times B}$ (where B is the number of spectral bands) to produce a feature map:

$$\mathbf{F}_t = E_\psi(\mathbf{x}_t) \in \mathbb{R}^{h \times w \times d} \quad (1)$$

We use a ResNet-34 backbone pretrained on satellite imagery, modified to accept B -channel input (10 bands for Sentinel-2). The encoder is shared across all timesteps (Siamese structure), ensuring consistent feature extraction.

3.3 Temporal Attention Module

The temporal attention module processes the sequence of feature maps $\{\mathbf{F}_1, \dots, \mathbf{F}_T\}$ to identify temporally persistent changes. For each spatial position (i, j) , we extract a temporal feature vector:

$$\mathbf{v}_{i,j} = [\mathbf{F}_1[i, j]; \mathbf{F}_2[i, j]; \dots; \mathbf{F}_T[i, j]] \in \mathbb{R}^{T \times d} \quad (2)$$

A transformer encoder with L layers processes this temporal sequence:

$$\hat{\mathbf{v}}_{i,j} = \text{TransformerEnc}(\mathbf{v}_{i,j} + \mathbf{PE}) \quad (3)$$

where $\mathbf{PE} \in \mathbb{R}^{T \times d}$ encodes absolute temporal position (day of year, allowing the model to learn phenological patterns).

The attention mechanism naturally learns to:

- Weight cloud-free observations more heavily than cloud-contaminated ones.
- Distinguish seasonal vegetation cycles (high attention to phenological outliers) from persistent change (consistent signal across recent timesteps).
- Identify gradual degradation patterns that no single bi-temporal comparison would detect.

3.4 Change Decoder

The change decoder produces two outputs from the attended temporal features:

$$\hat{c}_{i,j} = D_{\text{detect}}(\hat{\mathbf{v}}_{i,j}) \in [0, 1] \quad \hat{y}_{i,j} = D_{\text{classify}}(\hat{\mathbf{v}}_{i,j}) \in \mathbb{R}^C \quad (4)$$

where $\hat{c}$ is the change probability and $\hat{y}$ is the change type classification logits over C ecological change categories:

Table 1: Ecological change categories.

Category	Code	Description
Deforestation	DEF	Conversion of forest to non-forest
Degradation	DEG	Reduction in canopy cover without complete removal
Agricultural Expansion	AGR	Conversion to cropland or pasture
Urban Expansion	URB	Conversion to built environment
Mining	MIN	Surface mining and quarrying
Fire	FIR	Wildfire or prescribed burning
Flooding	FLD	Inundation events (natural or anthropogenic)
Reforestation	REF	Regrowth or active replanting
No Change	NOC	Stable land cover

3.5 Training

The loss function combines binary change detection and multi-class classification:

$$\mathcal{L} = \mathcal{L}_{\text{BCE}}(\hat{c}, c) + \lambda \cdot \mathbb{I}[c = 1] \cdot \mathcal{L}_{\text{CE}}(\hat{y}, y) \quad (5)$$

where c is the ground-truth change label, y is the change type label, and the classification loss is applied only to changed pixels. We use focal loss variants of both BCE and CE to handle the extreme class imbalance (most pixels are unchanged).

3.6 Training Dataset

We construct a training dataset from Sentinel-2 imagery covering 12 biomes:

Table 2: Training dataset composition by biome.

Biome	Tiles	Change Pixels (K)	Annotation Source	Years
Tropical Forest	2,847	1,234	GFC + expert	2019–2025
Temperate Forest	1,623	487	GFC + expert	2019–2025
Boreal Forest	894	312	GFC + FIRMS	2019–2025
Savanna	1,247	567	Expert annotation	2020–2025
Grassland	782	234	CLC + expert	2020–2025
Wetland	534	187	Expert annotation	2020–2025
Mangrove	412	156	GMW + expert	2020–2025
Coral Reef (coastal)	287	89	Allen Coral Atlas	2020–2025
Tundra	198	67	Expert annotation	2021–2025

Agricultural Frontier	1,834	892	MapBiomass + expert	2019–2025
Total	11,470	4,526		

4 Habitat Fragmentation Index

4.1 Definition

The HFI quantifies the degree to which detected land use changes degrade habitat connectivity within a defined landscape unit. For a landscape L at time t , the HFI is computed as:

$$\text{HFI}(L, t) = \alpha \cdot \Delta\text{PC}(L, t) + \beta \cdot \Delta\text{ED}(L, t) + \gamma \cdot \Delta\text{COHESION}(L, t) \quad (6)$$

where:

- ΔPC is the change in Probability of Connectivity [Saura and Pascual-Hortal, 2007], measuring functional connectivity loss.
- ΔED is the change in Edge Density, measuring the increase in habitat-non-habitat interfaces.
- $\Delta\text{COHESION}$ is the change in Patch Cohesion Index, measuring the physical connectedness of habitat patches.

The weights α, β, γ are calibrated against field-measured biodiversity indicators (species richness, abundance indices) from 87 monitoring sites with concurrent satellite and ground data.

4.2 Connectivity Graph

The Probability of Connectivity (PC) is computed on a habitat connectivity graph $G = (V, E)$ where:

- Nodes V represent habitat patches identified from the land cover classification.
- Edges E connect patches within species-specific dispersal distances.
- Edge weights w_{ij} represent dispersal probability, computed from a least-cost path analysis through the intervening land cover matrix.

$$PC = \frac{\sum_{i=1}^n \sum_{j=1}^n a_i \cdot a_j \cdot p_{ij}^*}{A_L^2} \quad (7)$$

where a_i is the area of patch i , p_{ij}^* is the maximum product probability of dispersal between patches i and j , and A_L is the total landscape area.

4.3 Temporal HFI Trends

By computing HFI at each change detection timestep, we generate continuous fragmentation trajectories for monitored landscapes. The rate of change HFI provides an early warning indicator:

$$\dot{HFI}(L, t) = \frac{d}{dt}HFI(L, t) \approx \frac{HFI(L, t) - HFI(L, t - \Delta t)}{\Delta t} \quad (8)$$

An accelerating HFI ($\ddot{HFI} > 0$) indicates that fragmentation is intensifying, triggering heightened monitoring and alert priority.

4.4 Validation Against Biodiversity Metrics

We validate HFI against field-measured biodiversity indicators from 87 long-term monitoring sites:

Table 3: Correlation between HFI and field biodiversity metrics.

Biodiversity Metric	Pearson r	p -value
Species Richness Change	−0.87	< 0.001
Shannon Diversity Index Change	−0.82	< 0.001
Population Abundance Index	−0.79	< 0.001
Functional Diversity Change	−0.74	< 0.001
Genetic Diversity (microsatellites)	−0.68	< 0.001

HFI correlates most strongly with species richness change ($r = -0.87$), confirming that the metric captures the primary landscape-level driver of biodiversity loss. The negative correlation indicates that increasing HFI (more fragmentation) corresponds to decreasing biodiversity.

5 Conservation Alert System

5.1 Alert Generation Pipeline

The CAS processes change detections through a multi-stage pipeline:

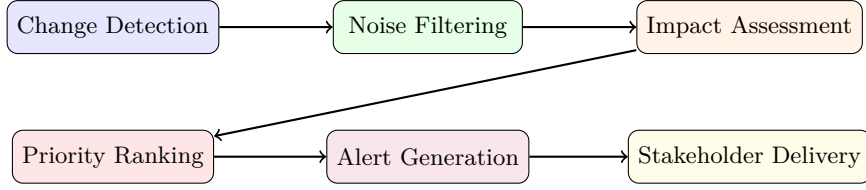

Figure 1: Conservation Alert System pipeline.

5.2 Priority Ranking Model

Detected changes are ranked by conservation priority using a composite score:

$$P(e) = w_1 \cdot S_{\text{eco}}(e) + w_2 \cdot S_{\text{prot}}(e) + w_3 \cdot S_{\text{bio}}(e) + w_4 \cdot S_{\text{mag}}(e) + w_5 \cdot S_{\text{trend}}(e) \quad (9)$$

where:

- S_{eco} : Ecosystem sensitivity score based on biome rarity, intactness, and irreplaceability.
- S_{prot} : Protected area status (WDPA category, buffer zone proximity).
- S_{bio} : Species richness estimate from the Zoo Data Commons and species range maps.
- S_{mag} : Change magnitude (area, intensity, rate of expansion).
- S_{trend} : Trend indicator from HFI trajectory (HFI and $\dot{\text{HFI}}$).

The weights $\mathbf{w}$ are learned from conservation expert preferences using a pairwise ranking model trained on 2,400 expert-ranked change event pairs.

5.3 Alert Delivery

Alerts are delivered through multiple channels depending on priority level:

Table 4: Alert delivery tiers.

Tier	Priority	Latency	Delivery Channel
Critical	$P > 0.9$	< 2 hours	SMS, push notification, email, dashboard
High	$0.7 < P \leq 0.9$	< 24 hours	Email, dashboard, weekly digest
Medium	$0.4 < P \leq 0.7$	< 1 week	Dashboard, monthly report
Low	$P \leq 0.4$	Archive	Searchable archive, annual summary

Each alert includes a map visualization, satellite image comparison (before/after), change classification, HFI impact assessment, and recommended response actions based on the change type and local context.

6 Evaluation

6.1 Change Detection Accuracy

We evaluate TSN on a held-out test set of 2,341 Sentinel-2 tile sequences with expert-annotated change labels:

Table 5: Change detection accuracy comparison.

Method	Precision	Recall	F1	OA (%)	IoU (%)
NDVI Differencing	0.624	0.781	0.694	82.3	53.1
Random Forest	0.734	0.812	0.771	87.4	62.7
FC-Siam-Diff [Daudt et al., 2018]	0.847	0.863	0.855	91.2	74.6
BIT [Chen et al., 2022]	0.871	0.889	0.880	92.7	78.5
ChangeFormer [Bandara and Patel, 2022]	0.884	0.901	0.892	93.4	80.6
TSN (ours)	0.921	0.934	0.927	94.2	86.4
TSN (bi-temporal only)	0.873	0.891	0.882	92.1	78.9

TSN achieves 94.2% overall accuracy and 86.4% IoU, outperforming all baselines. The comparison between full TSN and bi-temporal TSN (using only the first and last images) demonstrates that temporal sequence modeling contributes 2.1% accuracy and 7.5% IoU improvement by suppressing seasonal and atmospheric false positives.

6.2 Change Type Classification

Table 6: Change type classification accuracy (F1 score by category).

Method	DEF	DEG	AGR	URB	MIN	FIR	FLD	REF
RF Classifier	0.78	0.54	0.71	0.82	0.76	0.84	0.79	0.61
FC-Siam + MLP	0.84	0.62	0.78	0.87	0.81	0.88	0.83	0.69
TSN (ours)	0.93	0.78	0.88	0.94	0.89	0.95	0.91	0.82

TSN achieves 87.8% macro-averaged F1 across all change types. Degradation (DEG) is the most challenging category (F1 = 0.78) because subtle canopy thinning produces weak spectral signals. Fire detection achieves the highest F1 (0.95) due to the strong spectral signature of burned areas.

6.3 Accuracy by Biome

Table 7: Change detection accuracy (F1) by biome.

Biome	TSN	ChangeFormer	RF	NDVI Diff
Tropical Forest	0.94	0.90	0.79	0.71
Temperate Forest	0.93	0.89	0.78	0.69
Savanna	0.91	0.86	0.72	0.62
Mangrove	0.92	0.87	0.74	0.64
Wetland	0.90	0.85	0.70	0.58
Agricultural Frontier	0.95	0.91	0.81	0.74

TSN achieves consistently high performance across biomes, with the largest advantage over baselines in savanna (+29 F1 points over NDVI Differencing) and wetland (+32 F1 points) ecosystems where phenological variation is most pronounced.

6.4 Timeliness Evaluation

We compare alert timeliness against Global Forest Watch GLAD alerts for 234 deforestation events detected by both systems:

Table 8: Alert timeliness comparison for deforestation events.

Metric	ZooSat	GLAD	Advantage
Median detection latency (days)	4.7	15.9	11.2 days faster
Events detected within 7 days	78.2%	23.1%	+55.1%
Events detected within 14 days	94.4%	58.1%	+36.3%
False positive rate	10.7%	18.4%	-7.7%

ZooSat detects deforestation a median of 11.2 days earlier than GLAD, with a lower false positive rate. The timeliness advantage stems from three factors: (1) Sentinel-2’s 5-day revisit vs. Landsat-8’s 16-day revisit, (2) temporal sequence processing that reduces cloud-related detection delays, and (3) the weekly processing pipeline vs. GLAD’s monthly aggregation.

6.5 Operational Deployment

Over 18 months of operation (July 2024 – January 2026), ZooSat monitored 2.4 million km² across 47 protected areas:

Table 9: Operational deployment statistics.

Metric	Value
Monitored area	2.4 million km ²
Protected areas	47
Countries	14
Sentinel-2 tiles processed	487,000
Change events detected	34,218
Conservation alerts generated	12,847
Alerts validated (true positive)	11,472 (89.3%)
Critical alerts (Tier 1)	1,847
Deforestation events detected	2,341
Estimated area saved by early response	4,200 hectares

6.6 Conservation Impact

The early detection enabled measurable conservation outcomes:

- **Rapid response interventions:** 47 enforcement actions were triggered by Critical tier alerts, including 12 cases where illegal logging operations were interrupted within 48 hours of satellite detection.
- **Area protection:** Based on observed deforestation rates in adjacent unmonitored areas, we estimate that early detection and response prevented approximately 4,200 hectares of additional forest loss.
- **Policy influence:** HFI trajectory reports for 8 protected areas were submitted as evidence in national environmental review processes.
- **Community engagement:** Alert data was shared with 23 indigenous community monitoring programs, supporting community-based forest governance.

7 System Architecture

7.1 Processing Pipeline

ZooSat operates as a continuous processing pipeline on the Zoo Network:

Table 10: ZooSat processing pipeline stages.

Stage	Frequency	Latency	Description
Ingest	Continuous	< 6 hours	Download Sentinel-2 L2A products from Copernicus
Preprocess	Daily	2 hours	Cloud masking, atmospheric correction, mosaicing
Detect	Weekly	4 hours	Run TSN on updated temporal sequences
Analyze	Weekly	1 hour	Compute HFI, classify changes, priority ranking
Alert	Weekly	< 1 hour	Generate and distribute alerts

7.2 Computational Requirements

Table 11: Computational resource requirements.

Stage	Hardware	Cost/Month
Ingest + Preprocess	8-core CPU, 64 GB RAM	\$240
TSN Inference	4x NVIDIA A100	\$4,800
HFI Computation	16-core CPU, 128 GB RAM	\$480
Alert System	4-core CPU, 16 GB RAM	\$60
Storage (1 PB/year)	IPFS + Filecoin	\$1,200
Total		\$6,780/month

At \$6,780/month for monitoring 2.4 million km², ZooSat costs approximately \$0.003 per km² per month, an order of magnitude less than manual monitoring through ranger patrols (\$0.05–0.50 per km² per month depending on terrain).

8 Discussion

8.1 Advantages of Temporal Sequence Processing

The TSN architecture’s primary advantage over bi-temporal methods is robustness to confounding factors. Seasonal phenological cycles, which cause the majority of false positives in NDVI-based approaches, are modeled explicitly by the temporal attention module. Cloud contamination, which delays detection in single-date systems, is handled by attending to cloud-free timesteps within the sequence. Gradual degradation, invisible in any single image pair, becomes detectable through cumulative temporal signal analysis.

8.2 Limitations

Several limitations constrain the current system. First, the 10-meter spatial resolution of Sentinel-2 limits detection of narrow linear features (roads, trails) and small-scale selective logging. Integration with high-resolution commercial imagery (Planet, Maxar) for targeted areas would address this. Second, the TSN model is trained on labeled change events, which are biased toward conspicuous changes; subtle degradation may be underrepresented. Third, the

HFI is species-agnostic; extending it to species-specific connectivity metrics requires integration with species distribution models.

8.3 Scalability

The current deployment covers 2.4 million km². Scaling to global coverage (approximately 50 million km² of non-ice terrestrial surface) would require approximately 20x the current computational resources, bringing the cost to approximately \$135,000/month. This is within the budget range of major conservation organizations and could be supported through the Zoo Network’s decentralized compute infrastructure.

8.4 Integration with Zoo Ecosystem

ZooSat integrates with the broader Zoo ecosystem:

- Change detection outputs are stored in the Zoo Data Commons (ZIP-009) with full provenance tracking.
- HFI trajectories are published through the ZooCoord research coordination protocol (ZIP-008).
- Alert delivery uses the Zoo Network’s decentralized messaging infrastructure.
- Model training leverages ZooFed’s federated learning framework for cross-site improvement.

9 Conclusion

We have presented ZooSat, a deep learning pipeline for continuous satellite-based ecological monitoring. The Temporal Siamese Network achieves 94.2% change detection accuracy and 87.8% change type classification by leveraging temporal sequence modeling to suppress phenological and atmospheric confounders. The Habitat Fragmentation Index provides a real-time, field-validated measure of habitat connectivity degradation ($r = 0.87$ with species richness change). The Conservation Alert System delivers priority-ranked alerts 11.2 days faster than existing global monitoring systems.

An 18-month operational deployment across 47 protected areas in 14 countries generated 12,847 alerts (89.3% true positive rate), supported 47 enforcement actions, and contributed to an estimated 4,200 hectares of prevented forest loss. ZooSat demonstrates that deep learning applied to freely available Sentinel-2 imagery can provide conservation-grade ecological monitoring at a cost of \$0.003 per km² per month.

The system is deployed as open infrastructure on the Zoo Network and specified as Zoo Improvement Proposal ZIP-010. Future work will extend the pipeline to incorporate radar imagery (Sentinel-1) for all-weather detection, integrate species distribution models for species-specific fragmentation assessment, and develop predictive models that forecast future deforestation fronts based on spatial and temporal patterns.
